Identifying and managing adverse environmental health effects: 6. Carbon monoxide poisoning

Alan Abelsohn,* Margaret D. Sanborn,† Barry J. Jessiman,§ Erica Weir‡

Abstract

CARBON MONOXIDE POISONING IS AN ENIGMATIC ILLNESS. The symptoms are often non-specific or masked by an exacerbation of an underlying illness, such as congestive heart failure, that has been triggered by carbon monoxide inhalation. The effects can range from mild, annoying symptoms relieved by removal of the source to severe morbidity with profound central nervous system dysfunction, acute complications and delayed sequelae. Estimates suggest that about one-third of nonfatal cases of carbon monoxide poisoning go undetected and undiagnosed. We present a case of residential carbon monoxide poisoning to illustrate these points and to demonstrate the usefulness of a simple tool based on the CH2OPD2 mnemonic (Community, Home, Hobbies, Occupation, Personal habits, Diet and Drugs) that physicians can use to obtain an environmental exposure history. We outline the clinical management of carbon monoxide poisoning and provide strategies and resources to prevent exposure.

Case

A woman brings her 15-year-old son to their family physician in late November because he has had frequent headaches for 6 weeks. They are dull, frontal headaches that occur 2 or 3 times a week, usually in the morning and evening, and often resolve by the time the patient arrives at school in the morning. Associated symptoms include occasional dizziness, nausea, difficulty concentrating and fatigue. The boy has no previous history of headaches and no other remarkable medical history. The only medication he takes is acetaminophen on occasion to relieve the headaches. The patient has no known drug allergies and does not smoke or use recreational drugs or alcohol. The only significant family history is that the patient’s mother occasionally has migraines; she reports no recent increase in frequency. The patient appears healthy. The findings on physical examination are normal, as are the findings on examination of his ears, nose and throat, and cardiovascular, neurological and musculoskeletal systems. Because of the nonspecific signs and symptoms, the physician takes a brief environmental exposure history using the CH2OPD2 mnemonic (Community, Home, Hobbies, Personal habits, Diet and Drugs) to identify possible new sources of environmental contaminants (Table 1).1 The exposure history reveals that the patient’s bedroom was moved to the basement 4 months earlier, after he and his father had insulated and dry-walled the basement. The house is heated by a gas-burning furnace, and the family uses the wood-burning fireplace in the living room several times a week. The physician considers the possibility of exposure to carbon monoxide. The patient’s venous blood carboxyhemoglobin level is 5%. He advises the family to call the gas company and have the basement checked for carbon monoxide before they spend another night there. The gas company finds that the level in the home is normal.

How should the physician interpret this information and proceed?
Carbon monoxide is the product of incomplete combustion of hydrocarbons. It is colourless, odourless and nonirritating yet toxic. Readily absorbed through the lungs, carbon monoxide binds to hemoglobin as carboxyhemoglobin (COHb). Hemoglobin’s affinity for carbon monoxide is 200 to 250 times stronger than its affinity for oxygen. The absorption of carbon monoxide causes a leftward shift in the oxygen–hemoglobin dissociation curve, which results in decreased oxygen-carrying capacity and impaired release of oxygen to the tissues. This effect, together with impaired perfusion from hypoxic cardiac function, leads to cellular hypoxia. Fetuses are especially vulnerable to carbon monoxide exposure. Fetal hemoglobin has a higher affinity than adult hemoglobin for carbon monoxide, and therefore fetal COHb levels may significantly exceed maternal levels.

A low baseline level of 1%–3% carboxyhemoglobin in venous blood is detectable in all people from endogenous production. Tobacco smoke elevates this baseline level, as does exposure to carbon monoxide in the environment (Table 2). Motor vehicle exhaust is the most common outdoor source of carbon monoxide. Indoor sources other than tobacco smoke include exhaust from poorly ventilated gas- and oil-burning appliances and the infiltration of polluted outdoor air. The amount of carbon monoxide absorbed depends on the relative concentration in the environment, the duration of exposure and the patient’s minute volume. In relatively unpolluted ambient air, the concentration of carbon monoxide is 0.02–1.0 ppm. However, in urban areas it can be 10–20 times higher than that during periods of atmospheric stagnation (i.e., when temperature inversions occur in winter or when sedentary air masses occur in summer). In general, indoor levels rise and fall with outdoor levels, except in buildings with poorly ventilated combustion appliances. Carbon monoxide levels of about 115 mg/m3 (100 ppm) have been detected in the kitchens of some houses immediately after gas stoves were used for cooking. After reviewing the evidence, the Federal–Provincial Advisory Committee on Environmental and Occupational Health recommended that the acceptable short-term exposure ranges for carbon monoxide in resi-

Abelson et al
Carbon monoxide poisoning

History-taking tools such as the CHOPD mnemonic can help physicians direct general and more specific questions when screening patients for carbon monoxide poisoning (see box). Physicians may wish to use the more comprehensive environmental exposure history forms developed by the Environmental Health Clinical of Sunnybrook & Women’s College Health Sciences Centre (information on where to find these forms appears at the end of the article). Clues that point to an environmental exposure include more than one person being affected, pets being affected, the temporal relation of the symptoms to the use of the furnace, fireplace or venting fans, or a history of smoke inhalation.

The main indoor air pollutants that can cause headaches is carbon monoxide. Environmental tobacco smoke and volatile organic compounds can also cause headaches, but irritant symptoms of the eyes and throat are likely to be more prominent with those sources. The most common symptoms of carbon monoxide inhalation include headache, dizziness, weakness, nausea, difficulty in concentrating, shortness of breath and visual changes. Less frequent symptoms include chest pain, loss of consciousness, abdominal pain and muscle cramping. The circulatory and nervous systems are often affected because of their fixed oxygen needs: patients who have inhaled carbon monoxide may present with signs of myocardial ischemia, hypotension, congestive heart failure, arrhythmias, mental confusion, clumsiness, emotional lability, impaired judgement, diminished visual acuity, stupor or coma. Carbon monoxide poisoning is considered a “disease with a thousand faces.” Its classic mask — cherry-red lips, cyanosis and retinal hemorrhages — occurs only rarely. The signs and symptoms of nonlethal carbon monoxide poisoning, especially from intermittent, low-level exposures, are easily mistaken for other illnesses commonly seen in primary care, such as viral illness, depression, chronic fatigue syndrome, migraine or other headaches. Because viral illness and carbon monoxide poisoning both peak in incidence during the winter, the chance that the latter will be misdiagnosed increases in this season.

There appears to be no marker or constellation of signs or symptoms at presentation that predicts long-term outcome following carbon monoxide poisoning. Physicians must be alert to the possibility of delayed effects. An array of delayed neuropsychiatric signs and symptoms — the “neuropsychiatric syndrome” — has been observed in patients from 3 to 240 days after acute exposure, even in patients without initial signs of cerebral impairment immediately after exposure. The syndrome is estimated to occur in 10%–30% of carbon monoxide poisonings, but the reported incidence varies widely. Up to 10% of survivors show gross neurological or psychiatric impairment (e.g., parkinsonism, incontinence, dementia or psychosis), which is obvious to the physician. More frequent is the development of subtle, persistent neuropsychiatric deficits, including personality changes and cognitive deficits.

When carbon monoxide poisoning is suspected, COHb levels in venous blood should be measured. Normal levels are 1%–3% in nonsmokers and 4%–5% in smokers (levels as high as 9%–15% in smokers have been reported). Increased levels are diagnostic. However, the mean half-life of COHb is 320 minutes (range 128–409 minutes) in young healthy volunteers in room air, 80.3 minutes in people breathing 100% oxygen at 1 atmosphere and 23.3 minutes in those breathing 100% oxygen at 3 atmospheres. COHb levels may fall substantially by the time of presentation, especially in cases of recurrent, low-level exposures. Therefore, a normal COHb level does not rule out carbon monoxide poisoning. Arterial blood gas measurements may reveal a metabolic acidosis, a normal partial pressure of oxygen, a variable partial pressure of carbon dioxide and decreased oxygen saturation. However, in cases of mild carbon monoxide poisoning without respiratory distress, the evi-
idence from retrospective chart reviews has shown only a weak correlation between degree of acidosis, COHb levels and extent of neurological disability.28–29 Arterial blood gas analysis may not be as useful as the clinical impression of neurological disability in guiding treatment of mild carbon monoxide poisoning.30,31

A detailed neurological examination and neuropsychological testing should be performed to document any subtle abnormalities.2 CT and MRI scans may show widespread changes in the brain. The globus pallidus is the commonest site of abnormality.32 Changes in white matter are also commonly seen.30 The extent to which imaging changes correlate with clinical outcome, and the clinical value of neuroimaging, is disputed.30,31

People exposed to carbon monoxide must be treated immediately with high-flow oxygen, preferably 100%, at normal atmospheric pressure. There are no guidelines as to the length of the observation period. Most patients, including the case subject we have described earlier, can be treated in the primary care or emergency setting.3 Patients with severe carbon monoxide poisoning or those with associated underlying medical problems, especially cardiovascular disease, should be admitted to hospital, given oxygen as described above and monitored for cardiac arrhythmias. Classifying and treating patients primarily on the basis of COHb levels is inappropriate and potentially misleading.

The use of hyperbaric oxygen to treat severe cases is controversial.12–14 There is no evidence that unselected use of hyperbaric oxygen to treat such cases reduces the frequency of neurological symptoms at 1 month, and evidence from available randomized controlled trials is insufficient to provide clear guidelines for practice.15 The Undersea and Hyperbaric Medical Society recommends treatment with hyperbaric oxygen for patients with signs of serious intoxication regardless of their COHb levels.16 This includes patients with a history of unconsciousness and those with neurological signs, cardiovascular dysfunction or severe acidosis.

Whenever carbon monoxide poisoning is suspected, firefighters or the local gas company should be notified to investigate and correct the source of the problem; the investigators should be equipped with a breathing apparatus to protect against poisoning.2 Improperly designed or maintained household venting systems can cause a reversal of the continuous flow of flue gases and outdoor air, pulling them down the chimney instead of up — a process known as “backdrafting.”4 Elevations in ambient carbon monoxide levels at the source can be transient, especially if the problem is backdrafting with spillage of combustion product into the house.4 This can result in a normal reading that fails to identify a true problem. Consequently, it is sometimes necessary to take repeated measures at different times.

Prevention

The problems with diagnosis, treatment and delayed sequelae make the prevention of carbon monoxide poison-

The case revisited

How should the physician interpret the information and proceed?

There are 2 important findings: the case subject’s COHb level is 5%, and the carbon monoxide level in the basement, where the subject’s bedroom is located, is normal.

A COHb level of 5% in a person who does not smoke is definitely considered elevated, although headaches do not usually start until the level is over 16%. The half-life of COHb is short, about 3 hours, so it is likely that the patient’s level fell off substantially after he left the basement.
A normal level would not have definitively ruled out carbon monoxide poisoning as a cause of his headaches.

With regard to the normal carbon monoxide level in the basement, the important clue in this case is the timing of the headaches. They started in the fall, at the beginning of the heating season. On further questioning, a relationship was established between the headaches and the evenings when the fireplace was used. A heating, ventilation and air-conditioning contractor conducts a chimney flow test with the fireplace in use and finds a backdraft and concurrent carbon monoxide level of 75 ppm in the basement. When the lit fire in the livingroom consumed oxygen it caused a negative pressure in the inadequately ventilated house, including the furnace room in the basement, which resulted in the reversed flow of combustion gases, including carbon monoxide, down the chimney into the living area in the basement. The renovation that increased the insulation in the basement may also have contributed to increasing the backdrafting by reducing air flow and ventilation to the furnace. Reduced ventilation may also have allowed the concentration of carbon monoxide to increase.

It is imperative to treat the building as well as the patient. The family is advised to remedy the backdrafting by providing a fresh-air intake to the furnace and to install a carbon monoxide detector in the basement.

At a follow-up appointment the patient reports that he has had no more headaches and is feeling generally much better.

[Plotted exposure history questionnaire is available on the Ontario College of Family Physicians Web site (www.cfpc.ca) in the scrolling menu located in the middle of the page. The different components (Community, Home and Hobbies, Occupation, Personal habits, Diet and Drugs) can be printed on coloured paper for easy identification in patient charts. The questionnaire may be given to a patient to complete at home and bring to the next appointment for review and interpretation.]

Competing interests: None declared.

Contributors: Dr. Abelson conceived of and drafted the article. Drs. Gibson, Sanborn and Weir contributed to the conception of the review. All of the authors contributed to the revision of the manuscript and approved the final version.

Send us your interesting clinical images!

Through scopes and scanners, on film and computer screens, with ultrasonography and microscopy, clinicians capture stunning images of illness and healing. CMAJ invites you to share your normally privy visual perspectives on anatomy, pathology, diagnostic procedures and therapeutic techniques. Let colleagues outside your specialty take a close look at the characteristic signs of rare conditions (Kayser-Fleischer rings in Wilson’s disease) or the interior marvels of your clinical terrain (colonoscopic view of an adenomatous polyp). We’re also interested in images that take a wider angle on the context of care (a recently cord-clamped newborn on a cold steel scale). If you have original, unpublished images that are beautiful or informative, rare or classic, we’d like to include them in CMAJ’s Clinical Vistas.
